Don’t Forget to Gather the Evidence
Myocardial Effects of Cryoablation in the Immature Heart

J. Philip Saul, MD

In this issue of The Journal, Khairy et al present the results of an impeccably performed study comparing the effects of cryothermal (CRYO) and radiofrequency (RF) ablation on the developing swine heart. Despite the earlier report from my group in 1994 that RF lesions appear to grow when placed in the atria and ventricles of developing hearts,2 until now no parallel study has been published to assess the late effects of CRYO in the atria, ventricles, and AV groove of the immature heart. This lack of data may have come from a combination of limited funding sources and a form of complacency, perhaps based on early animal and human data demonstrating the relative safety of CRYO over RF techniques.4–7 All factors that may have led to acceptance of this new technology as preferable to RF for the developing heart. In fact, Khairy et al initially speculated that CRYO lesions would act differently than RF lesions at late follow-up, based on the different mechanisms of cell injury, and the distinct acute histological features of the lesions from the two techniques.4 When the data were in, they actually demonstrated that there were no differences between the late effects of CRYO and RF on developing myocardium, and both techniques led to long-term lesion growth and invasion of scar tissue into surrounding myocardium.1

New Devices and Drugs in Children
It is often the case in pediatrics that new technologies or drugs are adopted into clinical practice in the absence of animal or human data that sufficiently demonstrates both safety and efficacy in immature organs. This situation results from the combination of the immediate availability to pediatric providers of new drugs and devices once they are approved by the Food and Drug Administration (FDA) for adults and the lack of a requirement for pediatric testing for such therapies before approval. Because pediatric providers naturally desire to incorporate new therapies that might benefit their patients into their practices, in the absence of data they are required to make their own assessment of the balance between efficacy and safety. It would of course be preferable for data to be available before such decisions are made.

Important Observations From This Study
Khairy et al1 confirmed the findings of our earlier study of RF lesions that only atrial and ventricular lesions appeared to increase in size, whereas AV groove did not change significantly for either technology. This finding, which was also confirmed by Kriebel et al,12 can provide some comfort to the physician, since most ablations at every age are performed for AV groove related substrates (71% in infants and 89% in children).13 Saul et al2 suggested that transmurality of the lesions may have been a factor in lesion expansion. The data presented by Khairy et al1 does not allow for such an assessment, but it is worth noting that atrial and ventricular lesions both appeared to increase in size, despite only 39% of ventricular lesions being transmural, compared with 70% of atrial lesions. Further, lesion width, depth, and volume all increased with age. Finally, Khairy et al1 found evidence of endocardial surface disruption frequently in RF lesions but only rarely in CRYO lesions, potentially related to the development of more surface thrombi for RF than CRYO lesions. The presence of thrombus early after ablation with either technology (27% for RF and 14% for CRYO), even though aspirin was administered both before ablation and until death, suggest that at a minimum aspirin, therapy is an important therapeutic option for at least 30 days after ablation, regardless of the ablation technology, particularly when applications are delivered to left-sided structures.

It is also important to note that Khairy et al1 did not report on ablation affects to nearby coronary arteries in this study. However, 2 prior studies did demonstrate that CRYO can have minimal effects on nearby coronary arteries of infant pigs, with increased mural echogenicity by intracoronary ultrasound in 1 of 5 animals, and some lesion extension into the medial coronary wall of the left circumflex, without

123
stenosis or flow abnormalities. These changes were far less than those observed with RF lesions in prior studies. The report of Khairy et al demonstrates that both CRYO and RF energy application in immature hearts can cause late lesion expansion but does not directly address the acute safety issues of either technology. One conclusion might be that regardless of ablation technology, such procedures should not be performed in the youngest patients. The same could be said of cardiac surgery because there is evidence that cardiac surgical scars also expand with time in immature hearts. However, just as with cardiac surgery, in some infants, catheter ablation is clinically indicated, so the issue becomes one of using the safest available technology. In that regard, there are numerous features of cryoablation that raise its safety profile over RF energy when it comes to the smallest children. These include reversibility during testing, smaller lesion size, minimal effects on coronary arteries without reported stenosis, and minimal endocardial disruption with less thrombus formation. Many of these features were highlighted in the current study by Khairy et al.

The Future

It is clear that information such as that provided by this important study of Khairy et al is critical to optimizing clinical decision-making in the management of arrhythmias in small children. It appears that in growing myocardium, no form of myocardial injury or destruction, including surgically induced, can be accomplished with complete long-term safety. However, it is somewhat comforting to note that despite the observed lesion growth in animals with fibrous extension into surrounding myocardium, to date, late arrhythmias (>2 months after the procedure) have not been reported as a complication of infant ablation procedures.

Khairy et al add to the speculation on some of the cellular and biochemical mechanisms that might account for scar tissue expansion in the immature postnatal heart. These factors include differences between neonatal and adult hearts in myocardial cell division, fibroblast activity, growth factors, cytokine responses, matrix metalloproteinases, and other growth mechanisms, which can all influence the fibrogenic response. They end their report by stating “Further studies are required to elucidate the pathogenesis of ablation lesion growth in immature myocardium, identify potential therapeutic targets to limit lesion expansion, and assess the efficacy of preventive approaches.” I cannot agree more and would add that regulatory activities could help ensure that such information is sought for children in advance of public release of new devices by the FDA and that long-term follow-up of ablations performed in small children is warranted.
