Radiofrequency Ablation Versus Antiarrhythmic Medication for Treatment of Ventricular Premature Beats From the Right Ventricular Outflow Tract
Prospective Randomized Study
Zhiyu Ling, MD, PhD*; Zengzhang Liu, MD*; Li Su, MD, PhD; Vadim Zipunnikov, PhD; Jinjin Wu, MD; Huaan Du, MD, PhD; Kamsang Woo, MD; Shaojie Chen, MD, PhD; Bin Zhong, MD; Xianbin Lan, MD; Jinqi Fan, MD, PhD; Yanping Xu, MD; Weijie Chen, MD; Yuehui Yin, MD; Saman Nazarian, MD, PhD; Bernhard Zrenner, MD

Background—The purpose of this study was to compare the efficacy of radiofrequency catheter ablation (RFCA) versus antiarrhythmic drugs (AADs) for treatment of patients with frequent ventricular premature beats (VPBs) originating from the right ventricular outflow tract (RVOT).

Methods and Results—A total of 330 eligible patients were included in the study and were randomly assigned to RFCA or AADs group. The absolute number and the burden of VPBs on 12-lead Holter monitors were measured at baseline and at 1st, 3rd, 6th, and 12th months after randomization. Left ventricular ejection fraction was evaluated by transthoracic echocardiogram at baseline and at 3 and 6 months after randomization. During the 1-year follow-up period, VPB recurrence was significantly lower in patients randomized to RFCA group (32 patients, 19.4%) versus AADs group (146 patients, 88.6%; P<0.001, log-rank test). In a Poisson generalized estimating equations (GEE) regression model, RFCA was associated with a greater decrease in the burden of VPBs (incidence rate ratio 0.105; 95% confidence intervals [0.104–0.105]; P<0.001) compared with AADs. In a linear GEE model, the left ventricular ejection fraction had a tendency to increase after the treatment in both groups (coefficient, 0.584; 95% confidence intervals [0.467–0.702]; P<0.001). In a Cox proportional model, the QS morphology in lead I was the only predictor of VPB recurrence free for catheter ablation (hazards ratio, 0.154; 95% confidence intervals [0.044–0.543]; P=0.004).

Conclusions—Catheter ablation is more efficacious than AADs for preventing VPB recurrence in patients with frequent VPBs originating from the RVOT. QS morphology in lead I was associated with better outcome after ablation. (Circ Arrhythm Electrophysiol. 2014;7:237-243.)

Key Words: anti-arrhythmia agents • catheter ablation

Ventricular premature beats (VPBs) are the most common arrhythmia in clinical practice. The right ventricular outflow tract (RVOT) myocardium is frequently the source of VPBs or idiopathic ventricular tachycardia.1–3 Patients with frequent VPB recurrence was significantly lower in patients randomized to RFCA group (32 patients, 19.4%) versus AADs group (146 patients, 88.6%; P<0.001, log-rank test). In a Poisson generalized estimating equations (GEE) regression model, RFCA was associated with a greater decrease in the burden of VPBs (incidence rate ratio 0.105; 95% confidence intervals [0.104–0.105]; P<0.001) compared with AADs. In a linear GEE model, the left ventricular ejection fraction had a tendency to increase after the treatment in both groups (coefficient, 0.584; 95% confidence intervals [0.467–0.702]; P<0.001). In a Cox proportional model, the QS morphology in lead I was the only predictor of VPB recurrence free for catheter ablation (hazards ratio, 0.154; 95% confidence intervals [0.044–0.543]; P=0.004).

Conclusions—Catheter ablation is more efficacious than AADs for preventing VPB recurrence in patients with frequent VPBs originating from the RVOT. QS morphology in lead I was associated with better outcome after ablation. (Circ Arrhythm Electrophysiol. 2014;7:237-243.)
screened for enrollment in the study. Patients underwent review of history, physical examination, conventional 12-lead electrocardiography (ECG), 24-hour 12-lead Holter monitor, exercise stress test, transthoracic echocardiography, chest radiograph, as well as electrolyte, thyroid, hepatic, and renal function tests, before enrollment. MRI was also performed in patients with suspected arrhythogenic right ventricular cardiomyopathy (ARVC). The inclusion criteria were (1) frequent symptomatic VPBs from the RVOT documented by 12-lead ECG to have inferior axis and left bundle-branch block (LBBB) QRS morphology and (2) >6000 VPBs per 24 hours on Holter monitoring. The exclusion criteria included (1) the presence of non-RVOT origin for VPBs indicated by an S wave in lead I, R-wave duration index in V1 and V2 ≥0.5, and R/S wave amplitude index in V1 and V2 ≥0.3; (2) previous AADs therapy; (3) evidence of any structural heart disease; (4) hyperthyroidism or electrolyte disturbance; (5) drug toxicity; (6) diabetes mellitus; (7) blood pressure>165/100 mm Hg; (8) significant impairment of renal function; (9) QT interval>450 ms in the absence of bundle-branch block; and (10) significant atrioventricular conduction disease and left or right bundle-branch block. Of all patients screened, 330 patients were eligible for the study and provided written informed consent for participation. Figure 1 shows, schematically, the flow chart of participants in the study. The Ethics Committee of the second affiliated hospital of Chongqing Medical University approved the study protocol.

Study Protocol

A computer-generated list of random numbers was used for randomization. After the medical evaluation and diagnosis of idiopathic VPBs from the RVOT, patients were randomly assigned 1:1 to ablation or AAD group based on the computerized random numbers. Allocation concealment was safeguarded by ensuring that allocation was obtained by computer output after the patients had consented. AADs were administered in 165 patients, and the other 165 patients underwent RFCA. Crossovers were only permitted after 1-year follow-up or occurrence of the clinical end point. The AADs included metoprolol and propafenone, and were provided in an open-label fashion. Selection of metoprolol or propafenone was not randomized. If the patient had a higher VPB burden during daytime hours, then metoprolol was used. Otherwise, propafenone was selected. Initial doses of 12.5 mg bid for metoprolol and 100 mg bid for propafenone were recommended. Dosages of AADs were titrated up to the maximum based on clinical response and occurrence of side effects. Doses were reduced or discontinued if intolerable adverse reactions occurred.

Echocardiography

All patients underwent echocardiography to assess LV ejection fraction (LVEF) and dimension. The echocardiograms were digitized and analyzed off-line by an expert analyst who was blinded to patient status. LVEF was calculated using the Simpson biplane method.

Radiofrequency Catheter Ablation

In the presence of clinical VPBs, activation mapping was performed using a 4-mm tip ablation catheter. Pace mapping was performed in addition to activation mapping to identify the VPB focus during sinus rhythm. In patients without spontaneous VPBs, programmed...
ventricular stimulation was performed from the right ventricular (RV) apex and RVOT at 2 drive cycle lengths with up to 3 extra stimuli and incremental burst pacing at a cycle length up to 250 ms. In 3 patients, a 3-dimensional electroanatomic mapping system was used for activation mapping (CartoXP, Biosense Inc, Diamond Bar, CA). Radiofrequency energy was delivered with a 4-mm tip irrigated ablation catheter (Biosense Inc) in temperature-controlled mode with a target temperature of 45°C at a power of 30 W. If the VPBs were abolished within 20 seconds, the energy application was continued for 60 to 90 seconds followed by a second 60-second application. If VPBs were still present after 25 to 30 seconds, the energy application was terminated, and mapping was continued to find an optimal target site. Once the optimal target site was identified, it was documented on 2 orthogonal fluoroscopic views. After ablation, programmed ventricular stimulation and burst pacing on and off isoproterenol infusion were used to confirm the effectiveness of RFCA in all patients. Acute success was defined as the absence of VPBs with similar morphology during a 30-minute observation period.

Follow-Up
All patients were followed in the outpatient department within 2 weeks, and thereafter at monthly intervals, during which physical examination and 12-lead ECG were performed. Routine 12-lead Holter monitoring was performed at the 1st, 3rd, 6th, and 12th months, and echocardiography was performed at the 3rd and 6th months. When patients reported symptoms of palpitations, dizziness, or syncope during follow-up, they were advised to contact their doctors immediately for evaluation of vital signs, 12-lead ECG, and 12-lead 24-hour Holter monitoring. MRI was also recommended if worsening of LVEF or LV dimension was noted during the follow-up period. A 14-day blanking period was allowed for uptitration of medications before inclusion of events as clinical end points. The patients assigned to the RFCA group were AADs free after successful ablative procedures.

Study End Point
The primary end point was recurrence of RVOT VPBs at a rate of ≥300 beats per day documented by 24 h Holter monitoring. The secondary variables of interest including the number of VPBs, the burden of VPBs (the number of VPBs/total QRS complexes×100%), and LVEF at each follow-up time point were collected.

Statistical Analysis
All analyses were performed using the intention-to-treat principle. Continuous variables were presented as mean±SD or median (IQR: 25th percentile, 75th percentile) depending on normality of distribution and categorical values as frequency (%) (Table 1). Cox–Meier method was used to estimate time-dependent freedom from VPB recurrence among the study groups. Differences in VPB recurrence were assessed by the log-rank test. The Cox proportional hazards model was used to examine the association between treatment groups and VPB recurrence, the clinical characteristics including age, sex, VPB burden, duration of VPB symptoms, body mass index (BMI), LVEF, systolic blood pressure, and left atrial diameter (LAD) were included in the model to correct the potential imbalance between the 2 groups. The VPB burden was analyzed using a Poisson generalized estimating equations (GEE) model with the VPB numbers as the outcome variable, the heart beat numbers as an offset, and the visit time and treatment allocation as predictor variables. A linear GEE model was used to analyze the differences of LVEF during the follow-up visit. The interaction term between the predictor variables was examined in both GEE models. Cox proportional hazards regression analysis was used to identify independent predictors for VPB recurrence free in patients assigned to RFCA group. One-way ANOVA was used to test the differences of mean target focus activation times in QRS morphology subgroups of patients who received RFCA treatment. We also used a linear GEE model to analyze the association between LVEF and VPB burden with LVEF as outcome, and randomization group and VPB burden as predictors. A 2-sided P<0.05 was considered to indicate statistical significance. Statistical analysis was performed using STATA version 10.0 (STATA Corp, TX).

Results
The baseline characteristics of patients have been summarized in Table 1. Of 165 patients assigned to AADs, 50 patients received metoprolol, and 115 patients received propafenone. After the blanking period, the average doses of metoprolol and propafenone were 48.16±3.18 mg and 518.34±51.56 mg per day, respectively. At the end of the study, the average doses were 46.8±3.78 mg per day for metoprolol and 557.6±54.74 mg per day for propafenone, respectively.

Primary End Point
Of 5 patients that were lost to follow-up, 1 was in the RFCA group, and 4 patients were in the AADs group. The primary end point was reached in 32 patients assigned to RFCA and in 146 patients assigned to AADs therapy. As shown in Figure 2, the Kaplan–Meier survival analysis demonstrated a significant reduction in VPB recurrence in the RFCA group when compared with AADs therapy (P<0.001, log-rank test). The 1-year recurrence rate calculated with the KM estimate is 19.4% (95% confidence intervals [CI], 13.9–26.5) in RFCA group and 88.6% (95% CI, 82.5–92.8) in AADs, respectively. Compared with the AADs group, the relative risk reduction of VPB recurrence is 78.1% in RFCA group. Cox proportional hazards model analyzing showed that catheter ablation was associated with decreased VPB recurrence, both in models with (hazards ratio [HR], 0.088; 95% CI [0.058–0.131]; P<0.001) and without (HR, 0.094; 95% CI [0.062–0.139]; P<0.001) adjusting for age, sex, VPB burden, duration of VPB symptoms, BMI, LVEF, systolic blood pressure, and LAD.

Secondary End Points
The secondary end points including the burden of VPBs and LVEF at each follow-up visit for both groups have been summarized in Table 2. In a Poisson GEE regression model, RFCA group was associated with a greater decrease in the burden of VPBs (incidence rate ratio 0.105; 95% CI [0.104–0.105]; P<0.001) during the follow-up period (Table 2; Figure 3).

*Continuous variables are expressed as mean±SD or median (IQR: 25th percentile, 75th percentile); if not normally distributed, categorical variables are expressed as number (percentage).
Results from the linear GEE model suggested that LVEF had a tendency to increase after the treatment in both groups (coefficient, 0.584; 95% CI [0.467–0.702]; \( P < 0.001 \)), and this effect was not associated with group allocation (coefficient, 0.880; 95% CI [−0.283 to 2.044]; \( P =0.138 \)). In a linear GEE model, the VPB burden was negative associated with LVEF (coefficient, −0.192; 95% CI [−0.23 to −0.153]; \( P<0.001 \)).

**Effect of VPB Morphology on the Primary End Point in the Ablation Group**

All patients met the ECG inclusion criteria and lacked exclusion criteria as specified in the Methods section. There were 58 patients with QS morphology, 56 with rs/r's/r's', and 51 patients with qR/R/Rs in lead I. The mean procedural time was 82±35 minutes, and the mean fluoroscopy time was 13.5±9.8 minutes. The anatomic distribution of successful ablation targets for the 3 different QRS morphologies in lead I has been summarized in Table I in the Data Supplement.

As shown in Figure 4, the Kaplan–Meier survival analysis demonstrated a significant reduction of VPB recurrence in the QS morphology subgroup (\( P=0.005 \), log-rank test) when compared with other 2 subgroups. In a Cox proportional hazards regression model, QS morphology in lead I was the only significant independent predictor of VPB recurrence free (HR, 0.154; 95% CI [0.044–0.543]; \( P=0.004 \); Table II in the Data Supplement).

**Complications**

In RFCA group, 1 patient required cardioversion out of short-coupled triggered ectopy induced ventricular fibrillation (VF) during ablation in the RVOT septum. One arteriovenous fistula and 2 hematoma complications occurred after the procedure. All patients with complications recovered without residual symptoms before discharge.

In the AADs group, drug-related adverse effects were found in 17 patients. Three patients in the metoprolol subgroup and 4 patients in the propafenone subgroup developed symptomatic sinus bradycardia with heart rate<50 beats per minute, and 1 patient in the metoprolol subgroup and 2 patients in the propafenone subgroup developed symptomatic hypotension with blood pressure<90/60 mm Hg. Other adverse effects included 2 patients with mild fatigue and 1 with a cold extremity (with intact perfusion) in the metoprolol subgroup, and 3 patients with recurrent headaches and 1 with lower extremity edema in the propafenone subgroup.

AADs indicates antiarrhythmic drugs; IQR, interquartile range; LVEF, left ventricular eject fraction; RFCA, radiofrequency catheter ablation; and VPBs, ventricular premature beats.
QRS Morphology of VPBs in Lead I and RF Ablation Outcomes

Our data show that 87.9% of QS, 80.3% of rsr'/rsR', and 88.2% of qR/R/Rs morphology VPBs originate in the RV septum, anterior/posterior wall, and RV free wall, respectively. Additionally, the QRS morphology in lead I is strongly associated with outcome after ablation. Therefore, the QRS morphology in lead I can be used as a tool to predict the ablation outcome. In this study, we demonstrated that patients with QS morphology of VPBs in lead I had a better RFCA outcome than those with rsr'/rsR' and qR/R/Rs PVC morphologies. Krittayaphong et al10 demonstrated that monophasic R-wave in lead I was the only ECG predictor for unsuccessful RF ablation outcome. We presume that ablation outcome in patients with VPBs originating from the free wall of the RVOT is related to structural abnormalities, or proximity of the source to vascular structures that limit RFCA delivery and efficacy. Although there is no direct evidence to document structural abnormalities in patients with VPBs from RVOT, several studies have shown that structural abnormalities, such as localized wall bulging, wall thinning, fatty infiltration, and fibrosis, may be detected by MRI exist in the RVOT, not only in patients with ARVC19,20 but also in patients with RVOT tachycardia.21

Antiarrhythmic Drugs and Idiopathic VPBs

The majority of monomorphic ventricular ectopic activity is probably benign, especially in patients without obvious structural disorders. Treatment is often unnecessary. When the ectopic activity is symptomatic, the symptoms can be addressed by allaying the patient’s anxiety with reassurance. If this is not successful, the frequency of the ectopic beats may be reduced by administration of AADs.5 According to the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) guidelines,5 Class III AADs are not optimal as first-line AADs for the treatment of symptomatic ventricular tachycardia arising from the RV in patients with structurally normal hearts. Currently, sotalol and amiodarone are the only class III AADs choices in China. Considering the potential side effects associated with long-term use of class III AADs, we opted not to use these medications in the study.

We adopted strict criteria for the judgment of success in the RFCA group. To be consistent, we used the same primary end point criteria in both the RFCA and AADs groups. Because of these strict criteria, some patients (equal proportion in both groups) met the primary outcome despite having subjective improvement in symptoms. In this study, although both metoprolol and propafenone partly relieve symptom and reduce the burden of VPBs, the recurrence of VPBs was higher than RFCA. Therefore, class I and II AADs seem to be mildly effective, at best, for RVOT VPB suppression. Additionally, the side effects caused by long-term use of AADs should not be overlooked. Although no drug-related proarrrhythmic effect was documented in this group of patients, the potential hazards were noted in other studies.22,23

VPBs and Lethal Arrhythmias

Patient prognosis in the setting of VPBs from the RVOT is excellent in the absence of structural heart disease. However, lethal arrhythmias such as spontaneous VF and polymorphic
ventricular tachycardia can occur with short-coupled VPBs. No lethal arrhythmias were observed in this group of patients; however, the phenomenon has been noted by other investigators. In this setting, RFCA has been shown to be effective in eliminating VPBs and reducing the incidence of further VF recurrences. If short-coupled VPB or VPB triggered lethal arrhythmias are noted, RFCA might be the best choice.

Study Limitations
Several limitations may have influenced our results. First, although periodic 12-lead ECG and 24-hour Holter were performed during the follow-up period, episodes of asymptomatic VPBs or more serious arrhythmias might have been missed in some patients. Additionally, the study sample size and follow-up duration may have been insufficient to characterize the incidence fully of lethal arrhythmias among study groups. Second, other more potent AADS, albeit with greater side effects, were not used in this study. Third, a 1-year follow-up period may be insufficient to judge the long-term efficacy of either treatment modality.

Conclusions
The results of this study suggest that the efficacy of catheter ablation is superior to antiarrhythmic drugs for preventing VPB recurrence in patients with VPBs originating from the RVOT. QS morphology in lead I was associated with better outcome after ablation.

The right ventricular outflow tract (RVOT) myocardium is frequently the source of idiopathic ventricular premature beats (VPBs). Patients with benign but symptomatic frequent VPBs can be treated with antiarrhythmic drugs (AADs) or radiofrequency catheter ablation (RFCA) if their anxiety cannot be allayed with reassurance. However, few reports have compared the effects of AADs and RFCA. In this prospective randomized study, we compared the clinical efficacy of RFCA versus AADs for suppression of frequent VPBs from the RVOT. During the 1-year follow-up period, VPB recurrence was significantly lower in patients randomized to RFCA group when compared with that in patients randomized to AADs group, and RFCA was associated with a greater decrease in the burden of VPBs. In addition, the left ventricular ejection fraction had a tendency to increase after the treatment in both groups. The QS morphology in lead I was the predictor of VPB recurrence free for catheter ablation. The data of the present study demonstrate that catheter ablation is superior to antiarrhythmic drugs for preventing VPB recurrence in patients with VPBs originating from the RVOT, and QS morphology in lead I was associated with a better outcome after ablation. Therefore, despite a benign prognosis, our study suggests that RFCA should even be preferred for the treatment of symptomatic, idiopathic RVOT VPBs in those patients who do not wish long-term drug therapy.
