Catheter ablation is an established treatment option for patients with symptomatic drug refractory AF. In paroxysmal AF (PAF) ablation, pulmonary vein isolation (PVI) alone is a well-defined procedural end point. This strategy, although effective in maintaining sinus rhythm (SR) for PAF, has limited success in persistent AF (PsAF). The understanding of the substrate maintaining persistent AF remains rudimentary. The targets and end points of PsAF ablation are ill-defined, and there is no consensus on the optimal ablation strategy in these patients. Whether termination of AF by ablation is associated with a lower risk of recurrent arrhythmia compared with procedural failure to terminate AF with the need for electric cardioversion remains controversial.

Editorial see p 2

Finally, data on long-term outcome of PsAF ablation ≥5 years is limited, and the predictors of arrhythmia recurrence after PsAF ablation are ill-defined.
WHAT IS KNOWN

- In the population of patients with persistent atrial fibrillation (AF), the optimal selection for and the strategy of catheter ablation has yet to be determined. In addition, there is a scarcity of data with regard to multi-year outcome after persistent AF ablation.

WHAT THE STUDY ADDS

- Our study suggests that freedom from arrhythmia recurrence can be achieved by ablation in 65% of patients with persistent AF over 5 years of follow-up and in 74% when adding antiarrhythmic drug therapy. However, >1 ablation procedure is necessary in the vast majority of patients.
- In addition to patients’ symptoms, other characteristics, such as continuous AF duration, presence of structural heart disease, or left atrium diameter, should be used to decide with the patient whether ablation is a viable treatment option. Procedural AF termination strongly predicts favorable outcomes in patients undergoing substrate-based ablation for persistent AF.
- However, although most recurrences are observed during the first year, a slow but steady decline in arrhythmia-free survival is noted thereafter. Also, persistent AF ablation is still associated with a significant procedural complication rate.

The aims of this prospective observational study were 2-fold: (1) to determine the 5-year outcome in PsAF patients who underwent a stepwise ablation approach aiming at procedural AF termination and (2) to determine whether procedural AF termination and other baseline factors affect arrhythmia recurrence during long-term follow-up.

Methods

Study Population

The study population comprised 150 consecutive patients undergoing their first catheter ablation for persistent AF between November 2003 and October 2007 at our institution. Persistent AF was defined as continuous AF sustained beyond 7 days.1,2 Longstanding persistent AF was defined as persistent AF >12 months’ duration.1,2 As for inclusion criteria, a total AF history ≥6 months and a continuous AF duration ≥1 month were required. All patients had failed to maintain SR, despite cardioversion and treatment with ≥1 antiarrhythmic drug (AAD). Only patients who presented for the ablation procedure in AF were included. Baseline characteristics are summarized in Table 1. This study was approved by the institutional review committee of the University of Bordeaux Health System, and all patients gave written informed consent.

Electrophysiological Study and Ablation Procedure

Details of the peri-procedural management and the ablation technique at our institution have been described previously8,9,11,12,21–24 and are described in detail in the Data Supplement.

As it is standard clinical practice at our institution, all AADs were discontinued ≥5 half-lives before ablation, except for amiodarone (n=32). All patients received oral anticoagulation (target international normalized ratio 2–3) for ≥1 month before the procedure. Patients underwent transesophageal echocardiography within 48 h of the procedure to rule-out atrial thrombus. Warfarin was restarted the day after the procedure for 26 months after each ablation procedure and was continued thereafter at the physician’s discretion.

In all patients, sequential stepwise ablation was performed in the following order: PVI, electrogram-based ablation, and linear ablation. Circumferential PVI was performed with the end point of abolition or dissociation of electric activity of all PVs. When AF did not terminate during PVI, the procedure was continued with electrogram-based ablation in the LA. When electrogram-based ablation of the LA did not result in organization of the coronary sinus, additional ablation within the coronary sinus was performed. Linear ablation was performed if AF persisted after the previous ablation steps. A roof line was performed joining the right and left superior PVs, and if AF continued, a roof line was performed joining the right and left inferior PVs.

The primary procedural end point was termination of AF, which was defined as a transition directly from AF to SR or from AF to one or more atrial tachycardias (ATs) without AADs or electric cardioversion. Whenever AF terminated to one or more ATs, these were targeted for ablation until SR was achieved. When SR had not been restored by ablation, the AT was terminated by cardioversion. When AF was not terminated by ablation, SR was restored by cardioversion. Once SR was achieved, verification of entrance block of all PVs and bidirectional conduction block along all linear ablations was checked and, if necessary, supplemental ablation was performed as required to achieve block. No attempt at arrhythmia reinduction was made.

Values are given as n (%), mean±SD, or median (25th–75th percentile). AF denotes atrial fibrillation; AADs, antiarrhythmic drugs; LA, left atrium; LV, left ventricle; and TIA, transient ischemic attack.
Repeat procedures were performed targeting the documented recurrent arrhythmia and following the same stepwise approach aiming at arrhythmia termination.

Follow-Up
Patients were followed up at our institution 1, 3, 6, and 12 months postprocedure and every 6 months thereafter, including 24-h Holter monitoring. When patients had been asymptomatic and in SR for 12 months, they were followed up at our institution at 6 monthly intervals, including 24-h Holter monitoring. Patients referred from distant regions (n=12) were medically released 12 months after each procedure for regular follow-up with their local cardiologists as described, and every effort was made to update our clinical records with their progress and biannual Holter reports. Between visits, all patients were encouraged to seek ECGs or Holter monitoring for any symptoms suggestive of AF. The completeness rates for Holter monitoring were 96%, 91%, 90%, 85%, 83%, 79%, and 91% at 1, 2, 3, 4, 5, 6, and 7 years, respectively. Patients were personally contacted for a final follow-up between October 2011 and May 2012, and 7-day Holter monitoring (AFT-1000, Holter Supplies, France) was performed after this visit. The overall Holter completeness rate throughout the study was 89.7%.

AADs were continued for 1 to 3 months after the ablation procedure. Repeat ablation was offered to patients with arrhythmia recurrence after the initial 3-month follow-up period. The primary study end point was freedom from any asymptomatic or symptomatic atrial tachyarrhythmia lasting >30 s off AADs after the last ablation procedure. Regression of PsAF was defined as change to PAF or maintenance of SR on AADs.

Statistical Analysis
Continuous variables are presented as means±SD and median or interquartile range (interquartile range, 25th–75th percentiles). Categorical variables are presented as percentages (%) and counts. Two-group comparisons (ie, with or without AF termination during ablation; with and without amiodarone at the time of procedure) of continuous variables were performed by Student’s t tests if normally distributed or with Wilcoxon rank-sum tests if the normality assumption was violated according to Shapiro–Wilk tests or visual inspection of normal probability plots. Categorical variables were compared by chi-square tests. Baseline (ie, variables listed in Table 1) and procedural factors (ie, method of AF termination, procedural duration, and RF duration) associated with arrhythmia recurrence during follow-up were assessed in univariate and multivariable Cox proportional hazards models, from which hazard ratios and 95% confidence intervals were derived, after verification of proportional-hazards assumption by time-dependent interactions and goodness-of-fit statistics (weighted Schoenfeld residuals). Factors associated with P values <0.1 in univariate analyses were included in stepwise multivariate Cox regression models. A receiver–operator characteristic curve analysis was performed to determine the best cut-off value for the left atrial diameter and for continuous AF duration in predicting arrhythmia recurrence after the last ablation procedure. The value with the greatest discriminatory potential was selected on the basis of Youden’s Index. Time to first arrhythmia recurrence was calculated and plotted using the Kaplan–Meier product-limit method with comparisons performed by log-rank statistics. Two-tailed P values <0.05 were considered to indicate statistical significance. Baseline characteristics, including age, sex, comorbidities, and pharmacological therapy, were complete in all patients. Echocardiographic data were complete in 94%. Missing data were handled by listwise deletion (ie, complete case analyses). Statistical analyses were performed using SPSS 20.0 (IBM, Armonk, NY).

Results

Index Procedural Data
In 30 of 150 patients (20%), AF required pharmacological or DC cardioversion. (Figure 1) Of the 120 patients (80%) in whom AF terminated during ablation, 90 terminated via an intermediate step of AT and the remaining 30 converted directly from AF to SR. In those who terminated AF via AT, 75 patients could be successfully ablated to SR, whereas the remaining 15 patients required pharmacological or DC cardioversion to reach SR. A total number of 164 ATs (1.1±1.1 ATs per patient overall) occurred.

Compared with patients without AF termination, patients with AF termination had a shorter duration of continuous AF (12 [6–19] months versus 24 [17–44] months; P<0.001) and a smaller LA diameter (47±7 mm versus 52±8 mm; P<0.01).

The rate of AF termination was similar in patients with and without amiodarone at the time of the procedure (75% versus 81%, P=0.58). Mean procedural and RF durations for patients in whom termination of AF was achieved versus not achieved were 264±74 minutes versus 263±64 minutes (P=0.91) and 89±28 minutes versus 99±27 minutes (P=0.09), respectively.

Single Procedure Outcome
During a median follow-up of 70 (interquartile range, 60–81) months from the first ablation procedure until the last follow-up visit, SR was maintained in 23 of 150 (15.3%) patients after a single procedure. Arrhythmia-free survival rates after a single catheter ablation procedure were 35.3%±3.9%, 28.0%±3.7%, and 16.8%±3.2% at 1, 2, and 5 years, respectively (see online-only Data Supplement). Arrhythmia recurred in 30 (20.0%) patients who had maintained SR for ≥1 year, including 14 (9.3%) patients with recurrences >3 years after ablation. Recurrent arrhythmias after the index procedure were PsAF in 42 (33.1%) patients, PAF in 17 (13.5%) patients, and AT in 68 (53.5%) of 127 patients.

In multivariate analysis, the only factor independently associated with arrhythmia recurrence was failure to terminate AF during the index procedure (hazard ratio 1.650; 95% confidence interval, 1.086–2.513; P=0.02; Figure 2).

Multiple Procedure Outcome
One hundred nine patients (72.7%) underwent 167 repeat procedures (61 [36.5%] for AF and 106 [63.5%] for AT; Figure 3). Recovered PV conduction was found in 96/109 (88.1%) patients. Overall, PV ablation was performed in all 150 patients but was never the sole ablative strategy performed over the course of the study.

Figure 1. Procedural results of 150 patients undergoing their first AF ablation. AF indicates atrial fibrillation; AT, atrial tachycardia; DCC, electric cardioversion; LA, left atrium; RA, right atrium; and SR, sinus rhythm.
A total of 317 procedures were performed in 150 patients (2.1±1.0; median 2 [interquartile range, 1–3]). Forty-one (27.3%) patients had 1 procedure, 66 (44%) had 2, 31 (20.7%) had 3, 10 (6.7%) had 4, 1 (0.7%) had 5, and 1 (0.7%) had 6 procedures. The first and the last redo procedures were performed 11±13 and 19±19 months after the index procedure, respectively. During a median follow-up of 58 (interquartile range, 43–73) months after the last ablation procedure, 97/150 (64.7%) patients remained in SR without AADs and 111 patients (74%) remained in SR when including those on AADs (Amiodarone in 6 patients). Arrhythmia-free survival rates after the last catheter ablation procedure and off AADs were 89.7%±2.5%, 79.8%±3.4%, and 62.9%±4.5%, at 1, 2, and 5 years of follow-up, respectively (Figure 4), corresponding to an average actuarial recurrence rate of 8.5% per year. Event-free survival rates on or off AADs were 91.1%±2.4%, 83.0%±3.2%, and 70.4%±4.2% at 1, 2, and 5 years of follow-up, respectively. Regression of AF was noted in 29 (19.3%) patients: 14 (9.3%) patients maintained SR after reinitiation of AADs and 15 (10.0%) patients presented only with paroxysmal recurrences.

Factors associated with recurrent arrhythmias off AADs after the last ablation procedure are listed in Table 2. In multivariate analysis, independent predictors of recurrent arrhythmias were failure to terminate AF by ablation during the index procedure, structural heart disease, continuous AF duration ≥18 months, and an LA diameter ≥50 mm (Table 3). Freedom from recurrent arrhythmias did not differ according to whether AF was terminated in the RA or LA (P=0.83). Although the multiple-procedure success rate off AADs was lower in patients with long-standing persistent compared with persistent AF (55.1%±5.6% versus 77.8%±6.8%; P=0.01; Figure 5A), lack of AF termination during ablation was associated with a higher recurrence rate independent of whether AF was persistent or long-standing persistent (hazard ratio 3.831; 95% confidence interval, 2.070–7.143; P<0.0001).

Arrhythmia-free survival rates after multiple procedures on or off AADs did not differ between patients who terminated to directly SR versus to AT (83.1%±7.8% versus 80.0%±4.8%; P=0.92), but were significantly reduced for patients in whom ablation failed to terminate AF (29.3%±9.8%; P<0.0001; Figure 5B).
Complications

Complications occurred in 4.4% of procedures (pericardial effusion requiring intervention [n=6], phrenic nerve injury [n=3]; full recovery during follow-up), major femoral hematoma requiring intervention [n=2], cerebrovascular stroke [n=1]; full recovery during follow-up), myocardial infarction [n=1], and LA appendage isolation [n=1; no stroke during follow-up]). There were no procedure-related deaths. Three deaths occurred over the course of follow-up (skin cancer [n=1]; GI cancer [n=1]; postoperative death after mitral valve replacement [n=1]).

During long-term follow-up, 4 patients suffered an ischemic stroke. Two of these patients had previously failed AF ablation and were on warfarin with subtherapeutic international normalized ratio levels at the time of stroke and had CHA2DS2V-ASc scores of 2 and 3, respectively. The third patient had previously failed AF ablation and was on therapeutic warfarin, with a CHA2DS2V-ASc score of 4. The fourth patient had been in SR during follow-up and was off warfarin, with a CHA2DS2V-ASc score of 0. AF was documented during the hospitalization for stroke 49 months after the last AF ablation procedure. All patients recovered without major residual impairment.

Discussion

Our study reveals several important findings. First, it confirms that termination of PsAF can be achieved in most patients using a stepwise ablation strategy. Second, by 5 years of follow-up, freedom from arrhythmia recurrence is modest with a single ablation procedure, but can be achieved in the majority of patients by repeat ablation as needed. Third, a slow but steady decline in freedom from arrhythmia recurrence is noted during long-term follow-up, and predictors of arrhythmia recurrence include failure to terminate AF by ablation, a continuous AF duration ≥18 months, an LA diameter ≥50 mm, and structural heart disease.

Long-Term Outcome of Persistent AF Ablation

The concept of PVI as a treatment option for PAF is well established, with success rates of ≤80% during long-term follow-up.1,3 However, significantly less evidence exists for catheter ablation in PsAF patients.4 Knowledge of the long-term outcome of PsAF ablation is paramount to define its role in clinical practice. A recent study reported the long-term clinical outcome undergoing catheter ablation of longstanding PsAF using circumferential PVI in all patients, plus additional substrate modification in limited patients.5 During 56 and 50 months follow-up, single and multiple ablation procedure success was 20% and 45%, respectively. Circumferential PVI alone established long-term SR maintenance in only 24% of patients.6 These results raise the question whether circumferential PVI is the adequate ablation strategy for PsAF.

Haissaguerre et al first described the stepwise ablation approach in PsAF.7,8 Using this approach, Rostock et al reported a success rate of 79% after a median of 2.3 procedures with a median of 27 months of follow-up.13 Our study is the first to report on 5-year outcome in PsAF ablation aiming at AF termination as a procedural end point. To our knowledge, our study reports the highest long-term success rate in patients undergoing PsAF ablation. These results suggest that an ablation strategy beyond PVI may be of value in optimizing outcomes for PsAF.

However, the slow but steady decline in arrhythmia-free survival raises the question of whether ablation provides durable suppression of PsAF. Interestingly, arrhythmia recurred in 30 patients who had maintained SR for ≥1 year. It may be speculated that some recurrences of AF escaped earlier detection and that amiodarone may have masked some AF drivers during the index procedure, which later became manifest. These findings underscore the importance of careful long-term follow-up after AF ablation and have important ramifications regarding anticoagulation after PsAF ablation.

Impact of AF Termination

The other main finding of this study is that termination of PsAF by ablation can be achieved in the majority of patients and is the strongest predictor for freedom from arrhythmia recurrence during follow-up. Termination of AF may therefore represent a valid electrophysiological end point during PsAF ablation.

Reports dealing with the effect of AF termination on outcome are inconsistent. AF termination appeared to be a strong predictor of success in several studies.13,14 However, the rate of PsAF termination by ablation varies significantly between different approaches and centers. Although AF termination occurs in 16% of patients undergoing an anatomically guided circumferential PV ablation,14 termination rates of ≤87% are reported with the use of the stepwise ablation approach,11,17 including ≥20% of PsAF patients in whom PsAF is terminated during RA substrate modification.11,12

Scherr et al  Five-Year Outcome of Persistent AF Ablation 23

Clinical Implications
In the broad population of patients with PsAF, the optimal selection for and the strategy of catheter ablation has yet to be determined. Our study suggests that freedom from arrhythmia recurrence can be achieved in 65% of patients over 5 years of follow-up by ablation and in 74% when adding AADs. However, >1 ablation procedure is necessary in the majority of patients. In addition to patients’ symptoms, other characteristics such as continuous AF duration, presence of structural heart disease, or LA diameter should be used to decide with the patient if ablation is a viable treatment option. Procedural AF termination may predict favorable outcomes in patients undergoing substrate-based ablation. However, AF ablation in our study was associated with a significant procedural complication rate, consistent with the current worldwide experience with this procedure.1,22

Limitations
The current study describes results from a single experienced center, including a limited number of patients. Because of the high AF termination rate reported in our study, which required long and arduous procedures, these results may not be generalizable to all ablation centers treating persistent AF. Furthermore, these results require confirmation in a randomized controlled trial comparing different PsAF ablation approaches. Despite complying with recommendations regarding ECG monitoring for PsAF ablation1 with extensive efforts to detect asymptomatic recurrences, the potential for under-recognition of silent AF remains such that recurrence rates may have been underestimated.

Our study population represents a selected subgroup with persistent AF, such that results should not be extrapolated to all patients with PsAF.

Finally, the optimal ablation strategy for PsAF remains unknown, such that less extensive and more focused procedures may potentially achieve similar long-term efficacy in the future.23,24

Conclusions
In PsAF patients, a stepwise catheter ablation strategy with AF termination as a procedural end point and with repeat interventions as needed provides acceptable freedom from arrhythmia recurrence over a 5-year follow-up period. Procedural failure to terminate AF, PsAF duration ≥18 months, LA diameter ≥50 mm, and the presence of structural heart disease are predictors of arrhythmia recurrence. Although most recurrences are observed during the first year, a slow but steady decline in arrhythmia-free survival is noted thereafter.

SUPPLEMENTAL MATERIAL

SUPPLEMENTAL METHODS

Electrophysiological Study and Ablation Procedure

Details of the peri-procedural management and the ablation technique at our institution have been described previously.1-8 As it is standard clinical practice at our institution, all AADs were discontinued at least five half-lives prior to ablation except for amiodarone (n=32). All patients received oral anticoagulation (target INR 2–3) for \( \geq 1 \) month prior to the procedure. Patients with a contraindication to warfarin or who refused oral anticoagulation were treated with anti-platelet agents, at their physician’s discretion. Patients underwent transesophageal echocardiography within 48h of the procedure to rule out thrombus. Warfarin was restarted the day after the procedure for \( \geq 6 \) months after each ablation procedure and was continued thereafter at the physician’s discretion.

The following catheters were introduced via the right femoral vein: (I) a deflectable quadripolar or decapolar catheter (2–5–2 mm electrode spacing, Xtrem\textsuperscript{TM}, ELA Medical\textsuperscript{TM}, Le-Plessis- Robinson, France) positioned within the coronary sinus; (II) a 10 pole, fixed-diameter circumferential mapping catheter to guide PVI (Lasso\textsuperscript{TM}, Biosense-Webster\textsuperscript{TM}, Diamond Bar, USA), introduced with the aid of a long sheath (Preface\textsuperscript{TM}, Biosense-Webster\textsuperscript{TM}, Diamond Bar, USA, or SLOT\textsuperscript{TM}, St. Jude Medical\textsuperscript{TM}, St. Paul, USA); (III) a 3.5 mm irrigated-tip quadripolar ablation catheter (2–5–2 mm electrode spacing, ThermoCool\textsuperscript{TM}, Biosense-Webster\textsuperscript{TM}, Diamond Bar, USA). A single trans-septal puncture was performed in AP view with pressure monitoring.

Stepwise ablation was performed in the following sequence: PVI, electrogram-based
ablation, and linear ablation. The desired procedural endpoint was termination of AF without pharmacological or electrical cardioversion.

Circumferential PVI was performed with the endpoint of abolition or dissociation of electrical activity of all PVs. When AF did not terminate during PVI, the procedure was continued with electrogram-based ablation in the LA. Ablation targets included all sites in the LA displaying any of the following electrogram features: continuous electric activity, complex rapid and fractionated potentials, sites with an activation gradient between electrograms of the proximal and distal bipoles of the ablation catheter, and sites with local short cycle lengths compared to the LA appendage. The endpoint of ablation in each region was transformation of complex into discrete electrograms and slowing of local cycle length compared with LA appendage or elimination of electrograms. The RF delivery was also stopped after 60 sec of application per site.

When ablation of the inferior LA did not result in organization of the coronary sinus, additional ablation within the coronary sinus was performed, using the same electrogram-based criteria. Linear ablation was performed if AF persisted following the previous ablation steps. A roof line was performed joining the right and left superior PVs, and if AF continued, a mitral isthmus line from the mitral annulus to the left inferior PV was performed, with the endpoint of abolition of local electrograms.

Mapping and ablation using the same electrogram-based criteria were continued in the right atrium (RA) if AF did not terminate during LA ablation and the RA appendage demonstrated a shorter cycle length than the LA appendage. Linear ablation was performed in all patients at the cavo-tricuspid isthmus either before or after restoration of SR and bidirectional conduction block was confirmed.
