Abstract

Background: In primary prevention implantable cardioverter defibrillator (ICD) patients, the incidence of life-threatening ventricular arrhythmias resulting in ICD therapy is relatively low, prompting for better risk stratification. The aim of this study was to assess the value of the QRS-T angle for prediction of ICD therapy and mortality in primary prevention patients with ischemic heart disease (IHD).

Methods and Results: ICD patients (n=412, 361 male, age 63±11 years) with IHD and a left ventricular ejection fraction ≤ 40% were included. After device implantation, the occurrence of appropriate ICD therapy and mortality was noted. A survival analysis was performed comparing patients with a planar QRS-T angle ≤ 90º (n=124, 30%) to patients with a planar QRS-T angle > 90º before device implantation. Furthermore, patients with a spatial QRS-T angle ≤ 100º (n=56, 14%) were compared to patients with a spatial QRS-T angle > 100º, prior to implant.

For patients with a planar QRS-T angle >90º as compared to ≤ 90º, the adjusted hazard ratio for the occurrence of appropriate device therapy was 2.4 (95% CI 1.1-5.2); a spatial QRS-T angle > 100º was associated with an adjusted hazard ratio of 7.3 (95% CI 1.0-53.8).

Furthermore, a spatial QRS-T angle ≤ 100º exhibited a positive predictive value of 98% (95% CI 95-100%) for the prediction of an appropriate therapy-free follow-up.

Conclusions: A wide QRS-T angle is a strong predictor of appropriate device therapy in primary prevention ICD recipients with IHD. Furthermore, a spatial QRS-T angle ≤ 100º might be of value in the identification of patients in whom, although currently indicated, ICD treatment should be reconsidered.

Key Words: Implantable cardioverter defibrillator; electrocardiography, ventricular arrhythmia, primary prevention, ischemic heart disease
Introduction

Sudden cardiac death (SCD), mainly caused by ventricular arrhythmias, accounts for approximately 50% of all cardiac mortality worldwide.1-3 It is recognised that patients with ischemic heart disease and depressed left ventricular ejection fraction (LVEF) are at high risk of SCD,4,5 and large randomised trials have demonstrated that implantable cardioverter defibrillator (ICD) therapy reduces all-cause mortality, as well as SCD.6-10 Implementation of these results in the international guidelines resulted in a significant increase of the number of ICD implantations.11,12 However, long-term follow-up studies in currently indicated patients show a relatively low incidence of ventricular arrhythmias that trigger ICD therapy.13 Additionally, approximately 6% of ICD patients experience severe device-related adverse events (i.e. pocket infections, sepsis), causing the need for surgical re-intervention, additional hospitalization, or even death.14,15 This led to critical appraisal of the wide-spread application of ICD therapy and stressed the need for more precise risk stratification criteria.16 In an attempt to identify those criteria, post-hoc analyses of the second Multicenter Automatic Defibrillator Implantation Trial (MADIT II) revealed several clinical criteria associated with an increased risk for ventricular arrhythmias resulting in appropriate device therapy.17-19 So far, however, in low LVEF patients no criteria have been recognised which may identify patients at low risk of ventricular arrhythmias during follow-up. If possible to identify a low risk population, ICD therapy in this group may be reconsidered.

Recently, a wide angle between the QRS and T axes, the QRS-T angle, on the standard 12-lead ECG was recognised as a novel and easy applicable marker of increased risk for cardiovascular mortality.20,21 Subsequently, a wide QRS-T angle was found to be associated with the increased incidence of appropriate device therapy and mortality in primary prevention ICD recipients with non-ischemic cardiomyopathy.22 However, no data are available on the value of the QRS-T angle in ICD patients with IHD.

The aim of the current study was, to assess the value of the QRS-T angle in predicting life threatening ventricular arrhythmias in primary prevention ICD patients with IHD.
Furthermore the value of the QRS-T angle was evaluated as a parameter to identify patients at low risk for ventricular arrhythmias.

Methods

Patients

Patients with IHD who underwent implantation of an ICD, based on the international treatment guidelines, in the Leiden University Medical Center were selected for the current study. Criterion for inclusion were a depressed LVEF (<40%) with or without a history of non sustained ventricular tachycardia. Since 1996, these patients were prospectively registered in the departmental Cardiology Information System (EPD-Vision®). Prior to implantation, a comprehensive assessment of patient characteristics was performed as described previously.

During follow-up, the occurrence of appropriate ICD therapy and patient mortality was noted. In addition, for the purpose of this study, the ECG made before implantation was analyzed.

Implantable cardioverter defibrillator implantation and follow-up

All defibrillator systems were implanted transvenously without thoracotomy. Device follow-up was scheduled every three to six months. All printouts were carefully checked for appropriate and inappropriate ICD therapy. In case of any ICD therapy, an electrophysiologist, blinded to QRS-T measurements, determined whether or not the ICD therapy was appropriate. All therapies, either anti-tachycardia pacing (ATP) or shock, were classified as appropriate when they occurred in response to life threatening arrhythmias; ventricular tachycardia (VT) or ventricular fibrillation (VF) and as inappropriate when triggered by sinus or supraventricular tachycardia (SVT), T-wave oversensing, or electrode dysfunction.

Defibrillators were programmed as follows: ventricular arrhythmia faster than 150 bpm was monitored by the device without consequent defibrillator therapy. Ventricular
arrhythmias faster than 188 bpm were initially attempted to be terminated with two bursts of ATP and, after continuation of the arrhythmia, with defibrillator shocks. In the case of a ventricular arrhythmia faster than 210 bpm, device shocks were the initial therapy. Furthermore, atrial arrhythmia detection was set to >170 bpm with SVT discriminators enabled. Settings were adapted, only when clinically indicated (i.e. hemodynamic well tolerated ventricular tachycardia at high rate; ventricular tachycardia in the monitor zone).

**Electrocardiographical analysis**

First, the quality of ECGs was evaluated. If electrode displacement, missing leads or signal noise was present, the ECGs were excluded from the analysis. Since right ventricular pacing alters normal cardiac conduction and results, by definition, in an abnormal QRS-T angle, patients with a pacemaker were excluded from the analysis. Subsequently, the ECGs were analyzed with a dedicated computer program (LEADS, Leiden ECG Analysis and Decomposition Software). Full details on the computation method and LEADS based values of vector characteristics in healthy subjects, have been extensively described earlier. In short, the software converts the standard ECG into a vectorcardiogram and computes the three dimensional orientation of the QRS- and T-axes. Thereafter, the QRS-T angle is calculated in the plane formed by the QRS- and T-axes, the spatial QRS-T angle. In addition, the more commonly used but less precise projection of the spatial QRS-T angle in the frontal plane, the planar QRS-T angle, was computed. Previous studies demonstrated that a spatial QRS-T angle wider than 100° is associated with the presence of cardiac disease and increased cardiovascular mortality. Pavri et al. recently demonstrated that a planar QRS-T angle wider than 90° is associated with an increased incidence of appropriate device shocks and mortality. In the present study, these cut-offs (100° for the spatial and 90° for the planar QRS-T angle) were applied.

**Statistical analysis**
A survival analysis, comprising of the following end-points, was performed: (1) first appropriate ICD therapy (ATP and/or shock); (2) all-cause mortality; and (3) a composite end-point of all-cause mortality and first appropriate device therapy, whichever occurs first. ICD recipients with a narrow QRS-T angle were compared to those with a wide QRS-T angle. The points of cut-off were pre-defined as described above, 100º for the spatial and 90º for the planar QRS-T angle. Cumulative event rates of end-points were analyzed by the method of Kaplan-Meier. Relationships between baseline parameters and end-points were assessed with Cox’s proportional hazard regression analysis. For the composite end-point, survival time was defined as time to all-cause death or appropriate device therapy, whichever occurred first. For each variable a hazard ratio with a 95%-confidence interval (95% CI) was calculated.

Therapy-free follow-up was defined as a study follow-up without the occurrence of appropriate ICD therapy.

Continuous data are expressed as mean ± standard deviation or median and quartiles where appropriate, dichotomous data are presented as numbers and percentages. Comparison of data at baseline was performed with the Student’s t test for unpaired data and Chi-square tests with Yates correction when appropriate.

Results

Patients and follow-up

A total of 460 patients with ischemic heart disease and a LVEF ≤ 40% underwent ICD implantation for primary prevention of sudden cardiac death in the Leiden University Medical Center. Thirty-two (7%) patients were excluded due to the presence of a pacemaker and 16 (3%) patients were excluded since their ECG prior to device implantation could not be analyzed because of technical reasons such as electrode displacement, missing leads, or signal noise. The remaining 412 (90%) ICD recipients
(63±11 yrs, 88% male) were included in the analysis and were followed for 22±17 months (range 0 to 77 months). Baseline characteristics are summarised in Table 1.

During follow-up, 46 (11%) patients died, and a total of 482 episodes of appropriate device therapy for ventricular arrhythmias occurred in 56 (14%) patients; 386 episodes of ventricular arrhythmia, terminated by ATP in 35 (8%) patients, and 96 episodes triggering device shocks in 28 (7%) patients. During follow-up, the first end-point (first appropriate device therapy) was reached in 56 patients (24 shock, 32 ATP), the second end-point (all-cause death) was reached in 46 patients and the composite end-point (death or first appropriate device therapy) was reached in 96 patients (40 patients all cause deaths, 56 appropriate therapy).

QRS-T angle and all-cause mortality
In 124 (30%) patients, a planar QRS-T angle smaller or equal to 90º was measured on the baseline ECG. As summarised in Table 1, patients with a narrow planar QRS-T angle were more likely to be younger (61±11 yr vs. 64±10 yr, p<0.05), to have a better LVEF (28±7% vs. 25±7%, p<0.001), and shorter QRS duration (120±29 ms vs. 134±34 ms, p<0.001). The hazard ratio of a planar QRS-T angle > 90º for mortality was 3.1 (95% CI 1.3-7.3) as compared to patients with a narrow planar QRS-T angle. The cumulative event-free follow-up for all cause mortality in patients with a narrow planar QRS-T angle was 99% (95% CI 98-100%) at one year, 92% (95% CI 87-98%) at two years, and 92% (95% CI 87-98%) at four years of follow-up (Figure 1).

Fifty-six (14%) patients had a baseline spatial QRS-T angle smaller than or equal to 100º. These patients were younger, had a more preserved LVEF (30±6% vs. 26±7%, p<0.01), a shorter QRS duration (115±28 ms vs. 132±33 ms, p<0.01), used statins more often (95% vs. 83%, p<0.05) and were using amiodarone less frequently (2% vs. 16%, p<0.01) (Table 1). As is shown in Table 2, patients with a wide spatial QRS-T angle exhibited a hazard ratio for all-cause mortality of 1.7 (95% CI 0.6-4.9).
QRS-T angle and ventricular arrhythmia

The hazard ratio of a planar QRS-T angle wider than 90° for the occurrence of ventricular arrhythmia triggering appropriate device therapy was 2.9 (95% CI 1.4-6.1). When adjusted for age, sex, LVEF and QRS duration, the hazard ratio was 2.4 (95% CI 1.1-5.2). Furthermore, this group demonstrated an almost threefold risk increase (hazard ratio 2.9, 95% CI 1.6-5.0) for the composite end-point of appropriate therapy and mortality (Table 2). The cumulative event-free follow-up for appropriate therapy in patients with a narrow planar QRS-T angle was 95% (95% CI 90-99%) at one year, 93% (95% CI 87-98%) at two years, and 89% (95% CI 81-98%) at four years of follow-up (Figure 2).

As is shown in Table 2, patients with a wide spatial QRS-T angle exhibited a near tenfold risk for the occurrence of ATP or shocks (hazard ratio 9.9, 95% CI 1.4-71.7) during follow-up. When adjusted for age, sex, LVEF, and QRS duration the hazard ratio was 7.3 (95% CI 1.0-53.8). Strikingly, the cumulative event-free follow-up for ventricular arrhythmia which triggered device therapy was 100% at two years and 96% (95% CI 87-100%) at four years of follow-up, as can be readily seen in Figure 2.

Identification of patients free of life-threatening arrhythmias

Evaluation of the usefulness of a planar QRS-T angle smaller than or equal to 90° at baseline in the prediction of an appropriate therapy-free follow-up revealed a positive predictive value of 94% (95% CI 89-98%) and a negative predictive value of 17% (95% CI 12-21%).

The spatial QRS-T angle had a positive predictive value of 98% (95% CI 95-100%) and a negative predictive value of 15% (95% CI 12-19%) for the prediction of an appropriate therapy-free follow-up. Most importantly, only 2% of the patients with a spatial QRS-T angle ≤ 100° had appropriate device discharges during follow-up, the only event occurring after 745 days (Figure 2).

Discussion

In the current study on the clinical application of the planar and spatial QRS-T angle in the prediction of ventricular arrhythmias in ischemic primary prevention ICD patients, the main findings can be summarised as follows: after adjustment for age, sex, LVEF, and QRS-duration, 1) patients with a wide planar QRS-T angle exhibited a nearly 2.5-fold risk for mortality, as well as for appropriate device therapy; 2) patients with a wide spatial QRS-T angle had a sevenfold risk for ventricular arrhythmias triggering appropriate device therapy; and 3) patients with a spatial QRS-T $\leq 100^\circ$ prior to implantation, exhibited an absolute risk of 2% for appropriate therapy during follow-up.

With primary prevention ICD therapy as a class I indication in international guidelines in patients with a low LVEF, the indicated population, and therefore the worldwide defibrillator implantation rates, have increased significantly.\textsuperscript{11, 12} This expansion is of such magnitude that health care systems might lack the logistic capacity and financial means to meet the demand of ICD implantations.\textsuperscript{16, 28} Furthermore, MADIT II demonstrated a cumulative incidence of the need for defibrillator back-up of only 35% of patients after three years.\textsuperscript{13} Moreover, 6% of ICD treated patients, experience severe device-related adverse events.\textsuperscript{14} These issues underscore the need for better risk stratification within the indicated population.

Ideally, a parameter for the identification of a population at high or at low risk for the need for defibrillator back-up should be non-invasive and easily acquired. An ECG derived parameter such as the QRS-T angle, validated in the current analysis, would fit these demands.

Risk stratification with the QRS-T angle

The QRS-T angle is the angle between the electrical axes of depolarisation and repolarisation. In the present study, clinical application of both the planar as well as the spatial QRS-T angle has been investigated in primary prevention ICD recipients with ischemic heart disease. The planar QRS-T angle is the projection of the spatial QRS-T angle in the frontal plane. As with
any projection, it is sensitive to variations of the anatomical position of the heart in thorax. Therefore, the spatial QRS-T angle, which is calculated in the plane that the QRS- and T-axes form, is a more robust clinical tool. This is an important issue as the results from this study demonstrate that a narrow spatial angle is associated with a lower risk of ventricular arrhythmias. And although the spatial QRS-T angle cannot be derived directly from the surface ECG, recent studies have provided easy methods to acquire the spatial QRS-T angle from the standard 12-lead ECG.

In our population of ischemic primary prevention ICD recipients, patients with a wide planar QRS-T angle demonstrated a hazard ratio of 2.5 for the need of defibrillator back-up and 3.1 for all-cause mortality. In the recently published post hoc analysis of the DEFINITE trial, by Pavri and co-workers, the planar QRS-T angle was analyzed as a predictor of the composite end-point of appropriate device therapy, mortality, and resuscitated cardiac arrest in a population with non-ischemic cardiomyopathy. In this study, the hazard ratio of a planar QRS-T angle wider than 90° for the occurrence of appropriate device therapy was 1.95 (95% CI 1.24-3.08). The hazard ratio for all-cause mortality was 1.81 (95% CI 1.04-3.13).

After adjustment for other commonly used risk factors, the presence of a spatial QRS-T angle wider than 100° was associated with a hazard ratio of 7.3 for the occurrence of device therapy for ventricular arrhythmias as compared to patients with a spatial QRS-T angle ≤ 100°, in our population. More importantly, all patients with a spatial QRS-T angle ≤ 100° were free of device generated therapy during two years following implantation. This indicates that the spatial QRS-T angle may have an important potential for risk stratification in patients with ischemic heart disease.

Previous studies on the spatial QRS-T angle have already indicated its high value in the risk stratification for cardiac death in a population without ICDs. In a large cohort of patients, Yamazaki et al. observed a hazard ratio of 1.9 (95% CI 1.7-2.1) on cardiovascular death for a spatial QRS-T angle > 100° after correction for other ECG parameters.

As a consequence of the balanced regulation of electrical activation and recovery of the ventricles, a narrow QRS-T angle is generally observed in healthy individuals.
Ventricular scar or residual ischemia, which is the arrhythmic substrate in ischemic cardiomyopathy, causes a disbalance of this process, sometimes referred to as electrical heterogeneity or discordance of de- and repolarisation. Vectorcardiographically, these alterations in cardiac electrophysiology become, amongst others, apparent through directional changes of the QRS and T vectors and consequent widening of the QRS-T angle. When patients with ischemic cardiomyopathy have a narrow QRS-T angle, which is then associated with electrical homogeneity, it could be postulated that the amount of arrhythmic substrate is limited and may even be absent. The high incidence of ventricular arrhythmias in patients with a wide QRS-T angle and the low incidence in patients with a narrow QRS-T angle, as observed in the current study, underscores this principle.

Clinical implications

Several non-invasive parameters that could improve patient selection for ICD therapy have been proposed. These include LVEF, QRS duration, QT interval, heart rate variability, ventricular ectopy on ambulatory monitoring, exercise capacity, and T-wave alternans. In addition, total cosine R to T, which is also a measure of QRS-T concordance like the QRS-T angle, has been proven a promising parameter in the mortality risk stratification in patients following myocardial infarction. However, this variable has not been assessed in an ICD treated population, to our knowledge. Although the majority of these parameters appear promising, only LVEF has proven its usefulness in patient selection for ICD implantation and is currently the most important factor in the clinician’s choice whether or not an ICD is indicated. Still, in the implanted ischemic population, identified as being at high risk for ventricular arrhythmia based on depressed LVEF, 35% of patients actually experiences appropriate device therapy during follow-up, prompting for the identification of a sub-population at low risk. In our population of ischemic primary prevention ICD recipients, patients with a spatial QRS-T angle $\leq 100^\circ$ demonstrated no ventricular arrhythmias during the first two years following implantation and only 2% during further follow-up. These results imply that this parameter could be used in the discrimination of patients in whom the
beneficial effects of an ICD might not exceed the costs and potential morbidity accompanying ICD therapy.

Limitations
This was a non-randomised prospective observational study, performed to assess the long-term follow-up in ischemic primary prevention ICD recipients and to assess the value of the planar and spatial QRS-T angle in baseline risk stratification. Adjustment for additional variables in the multivariable Cox model was limited by the number of end-points reached. Furthermore, some patients without therapy during study follow-up might have reached an end-point, had follow-up been longer. Additionally, since not all patients had post-mortem ICD interrogation, some cases of death might have been arrhythmic. Finally, since patients were included over a period of 11 years, expanding guidelines for the implantation of defibrillators, treatment of acute myocardial infarction, and pharmacological anti-arrhythmic therapy could have created an inhomogeneous population.

Conclusion
In patients with ischemic heart disease, currently indicated for primary prevention ICD therapy, a baseline spatial QRS-T angle > 100° is associated with a sevenfold risk for the occurrence of appropriate device therapy, even after adjustment for commonly used risk factors. More importantly, a spatial QRS-T angle ≤ 100° on the ECG prior to implantation can identify patients with very low risk of life-threatening ventricular arrhythmias in whom the beneficial effect of ICD treatment might not exceed the costs and potential complications.
